

Finite time tracking of unilaterally constrained planar systems with pre-specified settling time: second order sliding mode synthesis and chattering-free digital implementation.

Harshal B. Oza, Vincent Acary, Yury V. Orlov, Sarah K. Spurgeon and Bernard Brogliato

Abstract—In this paper, tuning rules are established when a second order sliding mode controller is utilized to achieve finite time tracking for a class of unilaterally constrained planar systems in the presence of external disturbances in continuous and discrete-event phases. Rigid body inelastic impacts are incorporated at the unstable equilibrium. A numerical chattering-free digital implementation is also presented. This implementation, while being based on strong theoretical foundations, appears to bring the present advances in the area closer to industrial application.

I. INTRODUCTION

Dynamical systems with non-smooth vector fields and with unilateral constraints have been studied in various disciplines of science and engineering such as electrical engineering and robotics amongst others [1]. Establishing conditions for stability of such systems is a theoretical challenge due to the likely destabilizing effects of the unilateral constraints, resulting in state jumps. In this paper, planar controllable linear and feedback linearizable non-linear systems with unilateral constraints are studied. Unilaterally constrained systems can be studied as linear or non-linear complementarity systems [1]. The closed-loop dynamics of these systems are strongly affected by hard non-linearities characterized by both the nature of the contact of two bodies as well as collision, with the constraint resulting in a restitution in one of the states of a planar system. The existing literature is abundant on the topic of stability of systems with jumps (see [1], [2] and the references therein).

The main focus of this paper is on (i) finite time tracking of trajectories of the unilaterally constrained system to the desired periodic trajectories by using a second order sliding mode controller together with tuning of the controller parameters and (ii) digital implementation of the same. The theoretical motivation to study such a problem stems from several viewpoints. Firstly, asymptotic and finite time stability when impacts have a finite accumulation point have been studied for restitution coefficient in the interval $[0, 1)$ [1],

[3]. However, a priori guarantee and tuning to achieve finite time convergence for the tracking of periodic trajectories is not studied for the general case where restitution in the plant state is beyond the interval $[0, 1)$. Furthermore, robust finite time stabilization is theoretically an equally difficult challenge when compared to its asymptotic counterpart [2] provided that the effects of dissipative impacts tend to destabilize the system.

Secondly, research on robustness of the controller to disturbances at the time of state jumps is not rigorous. The present paper studies a similar class of systems to that presented in recent research [4] where a finite time observer is proposed to reject disturbances at the time of impacts. The presented result utilises tuning for a second order sliding mode (SOSM) controller [5] such that it is robust to persisting disturbances in both the continuous and discrete-event phases of the trajectories, while requiring only upper bounds on the uncertainties to cause the tracking errors to converge to zero in finite time between successive impacts.

Finally, existing results on numerical methods for sliding mode synthesis [6], [7] can be directly utilised for the tracking control of a unilaterally constrained system in the presence of impacts. A combination of the tuning of a robust SOSM synthesis that is based on the continuous time setting with the digital implementation, which matches the behaviour of the discrete time closed-loop system to that of the continuous time system at least in the case of no uncertainty, is theoretically novel for the underlying impact system.

From a practical viewpoint, the motivation stems from the need to propose tuning rules and digital implementation of SOSM for the presented class of systems. Following the recent advances in (i) Lyapunov methods for higher order sliding mode controllers and observers [8], [9], [10], (ii) finite time convergence and tuning [10] and (iii) numerical schemes [6], [7], a natural next step is to provide similar tuning and digital implementation for this problem. This problem is relevant in the area of biped robots and in general in fully actuated robots with unilateral constraints and thus has practical significance

The main contribution of the presented result is twofold. Firstly, the tuning rules for the controller are given for the presented tracking problem with an *a priori* guarantee of attaining a pre-specified settling time. The method differs from existing results [11] that depend on open-loop optimal control. The drawback of the presented method is that it is

more conservative. Nevertheless, it gives theoretical starting values for tuning that guarantee finite time tracking of the states of the hybrid system in the presence of disturbances in both continuous and discrete event (jump) phases. The second contribution is the ‘numerical chatter-free’ digital implementation of this SOSM controller for the tracking problem of a unilaterally constrained system resulting in reduced chattering in the presence of the aforementioned disturbances [7].

II. PROBLEM STATEMENT

Let the continuous system dynamics be given as follows:

$$\dot{x}_1 = x_2 \quad \dot{x}_2 = u + \omega(t) \quad (x_1, x_2) \notin \mathcal{S} \quad (1)$$

where x_1 is position, x_2 is velocity, u is the control law to be synthesized, $\omega(t)$ is an external disturbance, and the constraint surface \mathcal{S} is given by

$$\mathcal{S} = \{(x_1, x_2) : x_1 = 0\}. \quad (2)$$

The constraint surface gives rise to collision and induces resets in velocity $x_2(t)$. Let the velocity restitution (or impact event due to the unilateral constraint) be given according to the following Newtonian Reset Map:

$$x_2(t_k^+) = -\bar{e}x_2(t_k^-) + \omega_\Delta \quad (x_1, x_2) \in \mathcal{S} \quad (3)$$

where the notations $x(t_k^+)$ and $x(t_k^-)$ denote the right limit $\lim_{t \nearrow t_k} x(t_k)$ and the left limit $\lim_{t \searrow t_k} x(t_k)$ respectively, $\bar{e} \in [0, 1)$ is the restitution parameter responsible for the energy absorption [1], $t_k, k = 1, 2, \dots, \infty$ are the time instants at which these impulses occur and ω_Δ characterises the restitution uncertainty. Such an uncertainty ω_Δ represents a lack of complete knowledge of the linear reset map (3).

Let $(x_1^d(t), x_2^d(t) = \dot{x}_1^d)$ represent a desired trajectory of the same structure as that of the unilaterally constrained plant, i.e., the desired position is a continuous function of time whereas the desired velocity is piecewise continuous and it undergoes restitution in the opposite direction whenever $x_1^d(t) = 0$. The following assumptions are made throughout.

- 1) The desired trajectory $x_1^d(t), x_2^d(t)$ is a periodic function of time with period T^d such that $x_1(t) \neq 0 \quad \forall t \neq nT^d$ and $x_1(nT^d) = 0, n = 0, 1, 2, \dots$, thereby causing the periodic velocity restitution $x_2^d(nT^{d+}) = -K \text{sign}(x_2^d(nT^{d-}))$ with some positive constant K .
- 2) An impulse event occurs in infinitesimally small time. The impact event is detected.
- 3) $\text{ess sup}_{t \geq 0} |\omega| \leq N$ and $\text{ess sup}_{k \geq 0} |\omega_\Delta| \leq M_\Delta$ where N, M_Δ are *a priori* known positive scalars.
- 4) The upper bound \bar{R} on the quantity $\max\{|x_1(t_0)|, |x_2(t_0)|, |x_1^d(t_0)|, |x_2^d(t_0)|\}$, where t_0 is the initial time, is known *a priori* and is finite so that $\bar{R} > K + M_\Delta$.

The first assumption ensures that the chosen desired trajectory is periodic as the reset event in desired velocity $x_2^d(t)$ causes the post reset velocity $x_2^d(nT^{d+})$ to take the same value after every impact for all $n = 0, 1, 2, \dots$. For example, setting $x_1^d(t) = \frac{1}{2}\bar{\alpha}t^2 + \bar{\beta}t + \gamma$, where $\bar{\alpha} = -2\frac{K}{T^d}, \bar{\beta} = K, \gamma =$

0 are scalars, gives a periodic solution in the state-space (x_1^d, x_2^d) . Then, upon using a finite time stable controller to achieve $x_1 = x_1^d, x_2 = x_2^d$ before the next impact at t_k with settling time $T_{\text{tw}} < T^d$, the constraint surface becomes $S = \{(x_1, x_2) : x_1 = x_1^d = 0\}$. The second assumption is made simply to show the instantaneous nature of the impact event and to enable restitution in the desired velocity. The third assumption represents the upper bound on the uncertainty $\omega(t)$ and ω_Δ respectively. The last assumption dictates that the results presented in the paper are of a local nature¹. The following tracking dynamics can be obtained by defining the error variables $e_1(t) = x_1(t) - x_1^d(t), e_2(t) = x_2(t) - x_2^d(t)$:

$$\begin{aligned} \dot{e}_1 &= e_2 & \dot{e}_2 &= u(e) + \omega(t) - \dot{x}_2^d(t) & (x_1, x_2) &\notin \mathcal{S} \\ e_2(t_k^+) &= -\bar{e}x_2(t_k^-) + \omega_\Delta - x_2^d(t_k^+) & & & (x_1, x_2) &\in \mathcal{S} \end{aligned} \quad (4)$$

When $\dot{x}_2^d(t)$ is bounded, the first line of (4) coincides with the standard perturbed double integrator [5] and the twisting controller drives the errors e_1, e_2 to the origin in arbitrarily small finite time. Hence, it is guaranteed that the discrete event t_k and nT^d coincide. Furthermore, due to chatter-free numerical integration, the coincidence of t_k and nT^d holds true when the uncertainty $\omega = 0$ as in this case numerically integrated states match the continuous time counterpart identically even in sliding. However, t_k does not coincide with nT^d when ω is present since the discrete time states differ from the continuous time ones by the order dictated by the sampling time. When t_k coincides with the impacting time of the desired trajectories i.e. $t_k = nT^d$, then the impact law satisfies $e_2(t_k^+) = -\bar{e}x_2(t_k^-) + \omega_\Delta - K \text{sign}x_2^d(t_k^-)$. The aim of the paper is to propose (i) a switched state feedback synthesis, (ii) the corresponding tuning rules to establish the gains of the controller to give an *a priori* guarantee of finite time convergence of the states of system (4) to the desired trajectory and (iii) to propose a digital implementation of the proposed continuous time synthesis.

III. FINITE TIME TRACKING OF PERIODIC TRAJECTORY

The motivation to introduce the following definition is to accommodate the uncertainty at the time of impacts.

Definition 1: A unilaterally constrained system is said to possess finite time impact attenuation in the closed-loop if for every $\varepsilon > 0$, there exists an open neighborhood $\Omega_{\bar{R}}$ around the origin such that every solution $\phi(t)$ of (4) that satisfies $\phi(0) = p$, also satisfies (i) $\phi(t) = 0$ for all $t \in [nT^d + T_{\text{tw}}, (n+1)T^d)$ and for some $T_{\text{tw}} < T^d$ and (ii) $|\phi(t)| < \varepsilon$ for all $t \in [nT^d, nT^d + T_{\text{tw}})$ for all $p \in \Omega_{\bar{R}}$, where $n = 0, 1, 2, \dots, \infty$.

Remark 1: The uncertainty ω_Δ at the time of jumps in the actual plant velocity makes the error states deviate from the desired periodic trajectory at every jump and hence finite time stability can not in general be proven for all $t \geq 0$. This is the main motivation for the definition of finite time impact attenuation.

It should be noted that the differentiability of the solution $\phi(t)$ is not required. As will be shown in this section, this is

¹Such an upper bound is generally known *a priori* for a large class of mechanical systems.

because it is possible to construct a switched synthesis for which an absolutely continuous solution $\phi(t)$ in the sense of Filippov [12] is shown to exist for all $t \in [nT^d, (n+1)T^d)$ where $n = 0, 1, 2, \dots, \infty$. Let the switched control synthesis be given as follows:

$$u(e_1, e_2) = \begin{cases} Le, & (e_1, e_2) \notin \Omega_R; \\ \Phi(e), & (e_1, e_2) \in \Omega_R, \end{cases} \quad (5)$$

where,

$$L = \begin{bmatrix} -l_1 & -l_2 \end{bmatrix}^T, \Phi(e) = -\mu_1 \text{sign}(e_2) - \mu_2 \text{sign}(e_1) \\ \Omega_R = \{(e_1, e_2) : \mu_2 |e_1| + \frac{1}{2}e_2^2 \leq R\}. \quad (6)$$

Let the following *a priori* tuning rules be utilised:

$$\begin{aligned} \mu_1 &> \max \left\{ N, \frac{2\delta}{\mathcal{F}_{s_2} \sqrt{1-\eta^2}} + N \right\} \\ \mu_2 &> \max \left\{ \sqrt{\frac{R}{2}}, \frac{\mu_1 - N}{\eta}, \mu_1 + N, \rho \sqrt{\frac{R}{2(1-\rho)}}, \rho, \beta \mu_1 \right\} \\ l_1 &= \alpha \lambda^2, \quad l_2 = (\alpha + 1) \lambda \end{aligned} \quad (7)$$

where

$$\begin{aligned} \lambda &\geq \sqrt{\frac{2\mu_2 N + (\alpha+1)^2 N^2}{r}}, \quad \delta > \begin{cases} \frac{r_1(\beta+1)}{\beta-1}, & \text{if } r_0 > \frac{r_1(\beta+1)}{\beta-1}; \\ \frac{r_0(\beta+1)}{\beta-1}, & \text{if } r_0 < \frac{r_1(\beta+1)}{\beta-1}, \end{cases} \\ \lambda &= \max \left\{ \sqrt{\frac{2\mu_2 N + (\alpha+1)^2 N^2}{r}}, \kappa \right\}, \quad r_2 = \frac{\rho R}{\mu_2} \\ & \left(\mu_2(\alpha+1)|e_{10}| + \frac{2\mu_2}{\kappa}|e_{20}| \right) e^{-\kappa \mathcal{F}_{s_1}} \\ & + \left(2\alpha^2 \kappa^2 e_{10}^2 + (\alpha^2 + 1)e_{20}^2 \right) e^{-\kappa \mathcal{F}_{s_1}} \leq R_1, \end{aligned} \quad (8)$$

$$\begin{aligned} \mathcal{F}_{s_1} &= \varepsilon_1 T^d, \quad \mathcal{F}_{s_2} = (1 - \varepsilon_1) T^d \quad \text{if } r_0 > \delta; \\ \mathcal{F}_{s_1} &= 0, \quad \mathcal{F}_{s_2} = \varepsilon_1 T^d \quad \text{otherwise;} \end{aligned} \quad (9)$$

$r_1 = \sqrt{2R}$, $r \in (0, r_2)$, $R_1 = R - r$, $\alpha > 1$ is an arbitrary scalar, $\beta > 1$ is a tuning variable, $\eta \in (0, \frac{1}{\beta})$, R is an arbitrary positive constant representing the switching boundary, $\varepsilon_1 \in (0, 1)$, $\rho \in (0, 1)$ are arbitrary scalars, $r_0 = \sqrt{(e_{10})^2 + (e_{20})^2}$ is the upper bound on the Euclidian norm of the system initial conditions where $e_{10} = e_1(t_0)$, $e_{20} = e_2(t_0) + M_\Delta = e_{20}$. It should be noted that there always exists a solution κ such that (9) is satisfied (and can be obtained using numerical optimization routines). The basis for this is that $\lim_{\kappa \rightarrow \infty} \kappa^2 e^{-\kappa t} = 0$ for all $t \geq 0$. The quantity on the left hand side of the inequality (9) can be viewed as a function of κ . The parameter μ_2 is a fixed entity on the left hand side of (9) due to the order in which the parameters μ_1, μ_2, l_1, l_2 are tuned. Furthermore, parameter μ_1 is a function of \mathcal{F}_{s_2} and parameters l_1, l_2 are functions of \mathcal{F}_{s_1} .

In the following, a switched discontinuous controller is utilised and hence, the vector field of the closed-loop system is discontinuous. Existing results [13] are not applicable and a new proof is required. An *a priori* guarantee stemming from (7) is utilised for obtaining finite time convergence to the origin between the impacts. In this case, the stability of the system can at best be defined in the sense of Definition 1 due to the uncertainty at the time of the jumps. The following result is in order.

Theorem 1: Assume that the trajectory $x_1^d(t), x_2^d(t)$ is designed such that assumptions (1), (2), (3) and (4) hold true. Then, the closed-loop system (4), (5) possesses finite time impact attenuation if the tuning rules (7) are employed for determining the gains l_1, l_2, μ_1, μ_2 .

Proof: Let the neighbourhood $\Omega_{\tilde{R}}$ around the origin be chosen as follows:

$$\Omega_{\tilde{R}} = \{\max\{|x_1(t_0)|, |x_2(t_0)|, |x_1^d(t_0)|, |x_2^d(t_0)|\} \leq \tilde{R}\} \quad (10)$$

The tuning rules (7) ensure that the error variables $(e_1(t), e_2(t)) \in \mathbf{R}^2$ settle to the origin $(0, 0)$ of the continuous dynamics in less time than T^d for all $(x_1(t_0), x_2(t_0), x_1^d(t_0), x_2^d(t_0)) \in \Omega_{\tilde{R}}$ when the parameters e_{10}, e_{20} are chosen greater than \tilde{R} in (7). See [10] for detailed mathematical proof. What remains to be proven is the existence of finite time impact attenuation.

The solutions of the closed-loop system are given in (12). The upper bounds N, M_Δ on disturbances $\omega(t), \omega_\Delta$ are sufficient to compute the largest time required by the trajectory to enter the level set Ω_R of the Lyapunov function $V(e_1, e_2) = \mu_2 |e_1| + \frac{1}{2}e_2^2$ in finite time when a linear controller is being used. Although the control u , when switched to the second order sliding mode controller, is discontinuous on the axes $e_1(t) = 0, e_2(t) = 0$, the continuous flow can be integrated piece-wise in each of the four quadrants

$$\begin{aligned} G_1 &= \{e : e_1 > 0, e_2 > 0\}, G_2 = \{e : e_1 > 0, e_2 < 0\}, \\ G_3 &= \{e : e_1 < 0, e_2 < 0\}, G_4 = \{e : e_1 < 0, e_2 > 0\}. \end{aligned} \quad (11)$$

The integrals (12) prove uniform boundedness of the states as a function of time in the neighbourhood B_{r_0} where B_{r_0} is a ball centered at the origin with a radius $r_0 > 0$. See [10] for detailed computation of the integrals in (12). Let the trajectory be analysed in the period $t \in [nT^d, (n+1)T^d)$ for any n . The scalar $e^0 = r_0 = \sqrt{e_{10}^2 + e_{20}^2}$ is the upper bound on the norm of the periodic initial conditions (or equivalently jumps) $e(nT^d)$ because $\tilde{R} > K + M_\Delta$.

By definition of the desired trajectory x_2^d , the time T^d between the two jumps is known. The switched controller $u(e_1, e_2)$ is tuned as per (7) to obtain an arbitrarily small settling time $T_{\text{tw}} < T^d$ for an arbitrary initial condition. Since $K < \tilde{R}$, all post-impact errors $e(nT^d)$ settle at the origin in less time than T_{tw} due to the fact that the upper bound M_Δ on ω_Δ is embedded in the tuning rules in terms of worst case value of e_{20} . Hence, it holds that for any arbitrary initial condition $e(nT^d) \in \Omega_{\tilde{R}}$ where $n = 0, 1, 2, \dots, \infty$, the continuous flow (12) of the system (4), (5) between the impacts settles at the point $e_1 = 0, e_2 = 0$ before the next jump event $t = (n+1)T^d$. Then it follows that the jumps in both the actual and the desired velocities occur at the same time $t = t_k = nT^d$. Hence, the trajectory of (4), (5) always passes through the point $(e_1, e_2, t) = (0, 0, nT^d)$, where $n = 0, 1, 2, \dots, \infty$.

In the presence of uncertainty ω_Δ , the system (4),(5) possesses finite time impact attenuation in the sense of Definition 1 as there exist finite scalars $\varepsilon > 0, \delta > 0, T_{\text{tw}} < T^d$ such that for all $\|(e_1(nT^d), e_2(nT^d))\| <$

$$\begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix} = \begin{cases} \begin{bmatrix} [\alpha e_{10} + \frac{1}{\lambda} e_{20}] e^{-\lambda t} - [e_{10} + \frac{1}{\lambda} e_{20}] e^{-\alpha \lambda t} + \int_0^t \frac{1}{\lambda} [e^{-\lambda(t-\tau)} - e^{-\alpha \lambda(t-\tau)}] \omega(\tau) d\tau \\ - [\alpha \lambda e_{10} + e_{20}] e^{-\lambda t} + \alpha [\lambda e_{10} + e_{20}] e^{-\alpha \lambda t} + \int_0^t [-e^{-\lambda(t-\tau)} + \alpha e^{-\alpha \lambda(t-\tau)}] \omega(\tau) d\tau \end{bmatrix}, & \text{if } e \notin \Omega_R; \\ e^{At} e(0) + \int_0^t e^{A(t-\tau)} B u(\tau) d\tau, & \text{otherwise.} \end{cases} \quad (12)$$

where,

$$e = [e_1 \quad e_2]^T, \quad A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad u(t) = -(\mu_1 - N) \text{sign}(e_2) - \mu_2 \text{sign}(e_1) \quad (13)$$

ε and $(e_1(nT^{d+}), e_2(nT^{d+})) \in \Omega_{\tilde{R}}$, the inequalities (i) $(e_1(T_{\text{tw}}), e_2(T_{\text{tw}})) = (0, 0)$ for all $t \in [nT^d + T_{\text{tw}}, (n+1)T^d)$ and (ii) $\|e(t)\| < \delta$, $\delta = \varepsilon + |M_{\Delta}|$ hold true $\forall t \in [nT^d, nT^d + T_{\text{tw}}]$. \square

Remark 2: The above theorem proves Lyapunov stability (and not asymptotic stability) of the proposed tracking problem. However, it proves finite time stability in the presence of impacts $\forall t \geq 0$ in the case of gains μ_1, μ_2, l_1, l_2 approaching infinity as this gives $T_{\text{tw}} \rightarrow 0$ (see [10] for theoretical proof).

IV. CHATTERING-FREE DIGITAL IMPLEMENTATION

In this section, a numerical chattering-free implementation of the second-order sliding mode control is presented. This implementation of sliding mode control has been developed previously on non-impacting systems [6], [7] and is mainly based on an implicit (backward) Euler discretization of the unperturbed state dynamics with impact

$$\begin{aligned} \dot{x}_1(t) &= x_2(t), & \dot{x}_2(t) &= u(t), & (x_1, x_2) &\notin \mathcal{S} \\ x_2(t_k^+) &= -\bar{e}x_2(t_k^-), & & & (x_1, x_2) &\in \mathcal{S} \end{aligned} \quad (14)$$

together with the twisting controller [5]

$$u(t) \in -\mu_2 \text{sign}(x_1(t) - x_1^d(t)) - \mu_1 \text{sign}(x_2(t) - x_2^d(t)). \quad (15)$$

The notation in terms of the inclusion in (15) outlines the fact that the function $\text{sign}(\cdot)$ is considered as a multi-valued mapping

$$\text{sign}(x) = \begin{cases} 1, & x > 0, \\ -1, & x < 0, \\ [-1, 1], & x = 0. \end{cases} \quad (16)$$

The time discretization of the impacting state dynamics follows the lines of Moreau's time-stepping scheme [14], [15]. As usual in complementarity theory [16], the symbol $x \perp y$ means that $x^T y = 0$. Moreau's time-stepping scheme for the nonsmooth dynamics with the impact law (3) reads as

$$\begin{cases} x_{1,k+1} = x_{1,k} + hx_{2,k+1}, \\ x_{2,k+1} = x_{2,k} + hu_{k+1} + \lambda_{k+1}, \\ \text{if } x_{1,k} + hx_{2,k} \leq 0, \text{ then } 0 \leq x_{2,k+1} + \bar{e}x_{2,k} \perp \lambda_{k+1} \geq 0, \\ \text{otherwise } \lambda_{k+1} = 0. \end{cases} \quad (17)$$

where $h = t_{k+1} - t_k$ is the sampling time. As in the previous work on implicit implementation of sliding mode

controllers [6], [7], the computation of the control input u_{k+1} is given by an implicit evaluation of the control law (15),

$$u_{k+1} \in -\mu_2 \text{sign}(x_{1,k+1} - x_1^d(t_{k+1})) - \mu_1 \text{sign}(x_{2,k+1} - x_2^d(t_{k+1})). \quad (18)$$

Contrary to event-driven schemes, the time discretization (17), (18) is solved in a single step without resorting to an event-location procedure. When an impact is not forecast ($x_{1,k} + hx_{2,k} > 0$), the value of the impulse λ_{k+1} vanishes and it remains to solve the generalized equation

$$\begin{cases} Wx_{k+1} = x_k + hBs_{k+1}, \\ e_{k+1} = x_{k+1} - x^d(t_{k+1}) \\ s_{k+1} \in \text{sign}(e_{k+1}) \end{cases} \quad (19)$$

with

$$W = \begin{bmatrix} 1 & -h \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & 0 \\ -\mu_2 & -\mu_1 \end{bmatrix}. \quad (20)$$

Rearranging (19) produces,

$$\begin{cases} e_{k+1} = q + Ms_{k+1} \\ s_{k+1} \in \text{sign}(e_{k+1}) \end{cases} \quad (21)$$

where $q = W^{-1}x_k - x^d(t_{k+1})$ and $M = hW^{-1}B$. The problem (21) appears as a Mixed Complementarity Problem (MCP), a well-known problem in the Mathematical Programming community [17] for which numerous solvers are available. When an impact is forecast ($x_{1,k} + hx_{2,k} \leq 0$), the problem is slightly more complicated as it is necessary to solve

$$\begin{cases} \begin{bmatrix} e_{k+1} \\ y_{k+1} \end{bmatrix} = p + N \begin{bmatrix} s_{k+1} \\ \lambda_{k+1} \end{bmatrix} \\ s_{k+1} \in \text{sign}(e_{k+1}) \\ 0 \leq y_{k+1} \perp \lambda_{k+1} \geq 0 \end{cases} \quad (22)$$

with

$$p = \begin{bmatrix} q \\ H^T(q + x^d(t_{k+1})) + \bar{e}x_{2,k} \end{bmatrix}, \quad H = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad (23)$$

and

$$N = \begin{bmatrix} M & W^{-1}H \\ H^T M & H^T W^{-1}H \end{bmatrix}. \quad (24)$$

Problem (22) is an MCP that can be easily solved. Once one of the problems (21) or (22) is solved, the control is computed according to

$$u_{k+1} = Bs_{k+1}. \quad (25)$$

V. NUMERICAL SIMULATIONS

In this section, numerical simulations are presented using the digital implementation developed above. Given a constant control input u_{k+1} for the time-step $[t_k, t_{k+1}]$, the simulations are performed by solving the dynamics with disturbances on $[t_k, t_{k+1}]$ as follows:

$$\begin{aligned} \dot{x}_1(t) &= x_2(t) + \omega(t), & \dot{x}_2(t) &= u_{k+1}, & (x_1, x_2) &\notin \mathcal{S} \\ x_2(t_k^+) &= -\bar{\epsilon}x_2(t_k^-) + \omega_\Delta, & & & (x_1, x_2) &\in \mathcal{S} \end{aligned} \quad (26)$$

For the sake of simplicity, Moreau's time-stepping (17) is used with the finer time-step $\tilde{h} \ll h$ to mimic the behaviour of the continuous time plant. This integration could also be performed with an accurate event-driven procedure using, for example, a zero-order hold integration before and after the impact. The numerical simulations are obtained with the SICONOS open-source package² dedicated to nonsmooth dynamical systems [15].

For all the simulations presented below, the initial conditions have been chosen as $(x_1^d(0), x_2^d(0), x_1(0), x_2(0)) = (0, 4, 0, 3)$. The desired trajectories $x^d(t)$ have been designed such that

$$x_1^d(t) = x_2^d(0)\left(1 - \frac{t}{T^d}\right), \quad x_2^d(t) = \dot{x}_1^d(t), \quad t \in [0, T^d], \quad (27)$$

and $x^d(t + nT^d) = x^d(t)$ for $t \in [0, T^d], n \in \mathbb{N}$. The coefficient of restitution $\bar{\epsilon}$ is set to 0.5. The aforementioned tuning steps have been carried out rendering the tuning variables as follows:

$$\begin{aligned} \rho &= 0.99, r = 0.16, R = 1.5, \epsilon_1 = 0.3, \eta = 0.45, \\ \beta &= 2.2, \alpha = 1.01. \end{aligned} \quad (28)$$

The tuning rules (7) can then be employed to compute the controller gains as follows: $\mu_1 = 3.787, \mu_2 = 9.165$. The value of K is chosen such that $K = x_2^d(0)$ and the desired period is chosen such that T^d is greater than 10 ($T^d = 12$ in the presented simulations). The tuning rules (7) are then applied with $T^d = 10$.

Figure 1 shows the finite settling time behavior of the closed-loop system with the proposed implicit digital implementation without disturbances for the sampling rate $h = 0.1$. It should be noted that a large error occurs after each impact due to the inelastic impact ($\bar{\epsilon} = 0.5$). Nevertheless, the control algorithm is able to track the desired trajectory in less than ten seconds and without numerical chattering. The next simulation is performed with the introduction of disturbances in both the continuous time-dynamics and discrete event dynamics. The disturbances are modeled:

$$\omega(t) = M \sin(\varphi t), \quad \omega_\Delta = M_\Delta \text{random}(t), \quad (29)$$

with the frequency $\varphi = 0.3$ and the upper-bound $M = 1, M_\Delta = 0.4$. The symbol $\text{random}(t)$ denotes a function that generates random values in $[-1, 1]$. Figure 2 shows the behavior for the same sampling rate $h = 0.1$. Between impacts, the control counteracts the continuous time disturbances $\omega(t)$. To complete this section on the numerical simulations, Fig. 3 shows

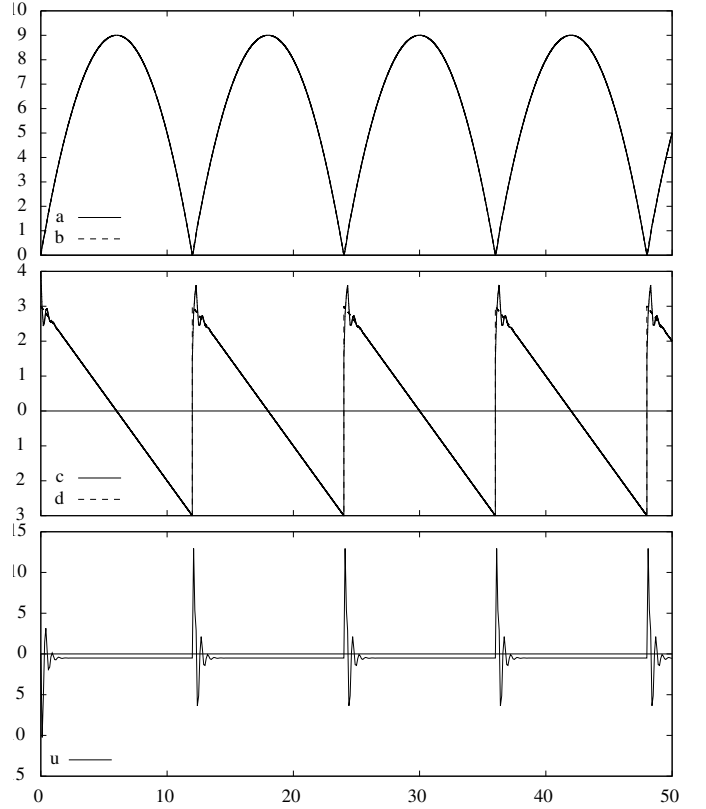

Fig. 1. Finite settling time behavior of the system (14),(15) between the impacts with the implicit digital implementation. a) position x_1 . b) desired position x_1^d . c) velocity x_2 . d) desired velocity x_2^d . e) control u . Sampling time $h = 0.1$.

the behavior of the system for $h = 0.1$ without disturbances and with the control defined using a standard (explicit) digital implementation of the control as follows:

$$u_k = -\mu_2 \text{sign}(x_{1,k} - x_1^d(t_k)) - \mu_1 \text{sign}(x_{2,k} - x_2^d(t_k)). \quad (30)$$

It should be noted that the numerical chattering due to the explicit implementation of the controller is not observed in the implicit implementation. It is noted, however, that increasing the sampling frequency will reduce the chattering magnitude and increase the frequency of chattering when an explicit integration scheme is used for the presented problem, numerical simulation of which is not presented due to want of space.

VI. CONCLUSIONS AND FUTURE WORK

Tuning rules are established when a second order sliding mode controller is utilized to achieve finite time tracking for a class of unilaterally constrained planar systems in the presence of external disturbances in continuous and discrete-event phases. Numerical chatter-free digital implementation is also presented. These results, while being based on strong theoretical developments, appear to make the latest advances in the area closer to industrial application. The results presented also have the potential for extension. Stability of periodic orbits can be studied via a method that computes the Poincaré maps and their Jacobian [1, Ch. 7,8].

Fig. 3. Standard (explicit) implementation of the second-order sliding mode control for the system (14),(15) without disturbances. a) position x_1 . b) desired position x_1^d . c) velocity x_2 . d) desired velocity x_2^d . u) control u . Sampling rate $h = 0.1$

This method requires explicit solutions of the closed-loop systems. The presented result is not a valid candidate for the aforementioned Poincaré based method as it relies on a mathematical proof involving geometric series [10]. It is then an interesting open problem to render the presented method a valid candidate for the aforementioned Poincaré impact map results and to develop a new methodology to compute the Jacobian of Poincaré maps when a finite time convergent SOSM synthesis is used.
